ABSTRACT

Influence diffusion estimation is a crucial problem in social network analysis. Most prior works mainly focus on predicting the total influence spread, i.e., the expected number of influenced nodes given an initial set of active nodes (aka. seeds). However, accurate estimation of susceptibility, i.e., the probability of being influenced for each individual, is more appealing and valuable in real-world applications. Previous methods generally adopt Monte Carlo simulation or heuristic rules to estimate the influence, resulting in high computational cost or unsatisfactory estimation error when these methods are used to estimate susceptibility. In this work, we propose to leverage graph neural networks (GNNs) for predicting susceptibility. As GNNs aggregate multi-hop neighbor information and could generate over-smoothed representations, the prediction quality for susceptibility is undesirable. To address the shortcomings of GNNs for susceptibility estimation, we propose a novel `DeepIS` model with a two-step approach: (1) a coarse-grained step where we estimate each node's susceptibility coarsely; (2) a fine-grained step where we aggregate neighbors' coarse-grained susceptibility estimations to compute the fine-grained estimate for each node. The two modules are trained in an end-to-end manner. We conduct extensive experiments and show that on average `DeepIS` achieves five times smaller estimation error than state-of-the-art GNN approaches and two magnitudes faster than Monte Carlo simulation.

1 INTRODUCTION

Social network users continuously generate massive contents, which could reach large audiences through information propagation. The prevalence of social networks expedites many social influence-based applications, e.g., viral marketing [17, 36] and recommendation [35, 44]. One essential problem is to predict the social influence. For example, a company may dispatch free products to some users as *seeds* and be interested in the number of users affected by the seeds through the *word-of-mouth* effect, i.e., they concern *how many users will be influenced in total* [17, 26]? However, in many real-world scenarios, predicting the probability of being influenced for targeted individuals (or **susceptibility**) is more appealing. In targeted advertising, the advertisers may consider the susceptibility of males/females, a certain age group, and other relevant information to craft the best marketing strategy [16, 28]. In political campaigns, influential ads for specific targets can significantly affect the election results [12]. Furthermore, susceptibility estimation could serve as a core component for a wide-known problem in social network studies: *Influence Maximization (IM)* [17, 26], which aims to select a seed set that could influence the most users.

Many existing studies have proposed diffusion models to characterize and analyze social influence, e.g., the Independent Cascade (IC) model [9] and the Linear Threshold (LT) model [11]. In this work, we focus on susceptibility estimation under IC and LT due to their popularity in the literature [5, 17, 20, 51], but our proposed approach can be adapted for other diffusion models. It has been proved that, computing the exact influence spread, i.e., the expected number of influenced users, under IC/LT model is #P-hard [5, 7]. Hence, most previous efforts adopt Monte Carlo (MC) simulation to estimate the influence spread, i.e., repeating the diffusion process and averaging the results [17, 25, 27, 30, 33, 51]. However, MC simulation is extremely time-consuming and cannot be scaled to large networks. Thus, some studies propose heuristic algorithms to approximate the influence spread, e.g., based on the node degree [6], the shortest path [5, 15] and others [15, 51]. While most existing methods focus on the influence spread and overlook the problem of estimating susceptibility for specific individuals or groups. According to our experiments in Section 5, adopting existing methods to estimate susceptibility can lead to high computational costs or unsatisfactory estimation error.

In this paper, we conduct the study on susceptibility estimation. The estimation problem can be regarded as a regression task on nodes. Thereby, we propose to tackle this problem from the graph learning perspective, leveraging graph neural networks (GNNs).

However, there are two major challenges in susceptibility estimation with GNNs. First, the influence diffuses through many users. To tackle the susceptibility for a specific node u, we should consider multi-hop neighbors of u. Meanwhile, GNNs aggregate multi-hop neighbors' information by stacking multiple layers, and each layer aggregates one-hop neighbors' information [18]. However, it has been shown that multiple stacked layers can lead to over-smoothed node representations [24] and tend to hurt the performance of any prediction task on individual nodes [48]. Second, GNNs aggregate neighbors' representations using uniform weight [18] or attention mechanism [43]. Thus, the aggregation schemes of GNNs do not capture specific characteristics of the underlying diffusion model.

To address the challenges, we propose a novel DeepIS model for susceptibility estimation. We integrate the characteristics of the diffusion model into DeepIS with a two-step approach. In the first step, we construct features by encoding the seed nodes into a multi-hot vector and taking the power sequence of the influence probability matrix. The features are then fed into a multi-layer GNN for coarse-grained susceptibility estimations. We adopt independent estimation on every node to eliminate the aggregation step from neighbors and thus circumvent the problem of over-smoothed representations of GNNs. In the second step, to enable fine-grained computation, we propose a propagation scheme to diffuses each node's estimation among its neighbors. We devise the propagation equation motivated by the concept of stationary distribution of the random walk process. Since the influence spread is intrinsically different with the random walk, we devise an iterative propagation scheme considering the specific characteristics of the diffusion dynamics. The model is trained in an end-to-end manner. We note that DeepIS is *inductive*, i.e., we could train the model on one graph and run on other graphs, which avoids expensive retraining on large datasets and enables real-time influence analysis.

We verify the efficacy of DeepIS on several public graph datasets. Experimental results reveal that DeepIS provides five times smaller estimation error compared with state-of-the-art GNN models and reduces about two orders of magnitude running time compared with MC simulation. Furthermore, DeepIS performs well as a subroutine of the IM problem. For convenient reproduction of the results, we release the implementation of DeepIS [1].

2 RELATED WORKS

In this section, we review the related literature on influence spread estimation as well as GNNs.

2.1 Influence Spread Estimation

Influence spread estimation approximates the expected number of influenced nodes given a seed set, and it is a core component in IM algorithms [5, 6, 17, 21]. Computing the influence spread exactly under IC /LT model is #P-hard [5, 7].Hence, the MC simulation is adopted to estimate the influence spread [10, 21, 33, 51]. Some recent works adopt the sampling of reverse reachable (RR) sets to estimate the influence spread [1, 41, 42]. RR sets-based estimation can be regarded as a specific MC method. To alleviate the computational overhead of the MC simulation, [6] proposes to utilize the node's outdegree and a discount rule to approximate the marginal influence spread. [15] approximates the marginal influence spread of a single node by iteratively computing a system of linear equations.

Another line of works utilizes GNNs to predict the influence spread or the node states. [22, 35] utilize the neighbor nodes' states and the local subgraph to predict a node's activation state. [3, 23, 49] aim to predict the popularity of social contents based on the cascade information in a time window. They conduct predictions based on message cascade logs. Note that this line of works does not consider the influence diffusion models. Furthermore, all existing works focus on predicting the total number of influenced nodes without considering the susceptibility of individual nodes, which are not suitable for targeted influence analysis studied in this work.

2.2 Graph Neural Networks

GNNs are getting surged attention in recent years. As deep neural networks have achieved widespread success in the Euclidean data space, GNNs mainly focus on the non-Euclidean graph structures. The general paradigm of GNNs alternates between node feature transformation and neighbor nodes' information aggregation. For a k-layer GNN, a node aggregates information within k-hop neighbors. Specifically, the k-th layer transformation is

$$a_v^{(k)} = \text{AGGREGATE}^k\left(\left\{h_u^{(k-1)}, u \in \mathcal{N}(v)\right\}\right) \tag{1}$$

$$h_v^{(k)} = \text{COMBINE}^k\left(\left\{h_v^{(k-1)}, a_v^{(k)}\right\}\right) \tag{2}$$

where $a_v^{(k)}$ represents node v's aggregated feature vector from neighbors, and $h_v^{(k)}$ is the k-th layer feature vector. The flexibility of AGGREGATE and COMBINE function induces different GNN models. The high-level representations of nodes or graphs are utilized for different tasks. GNNs have been applied in various learning tasks related to graphs, e.g., semi-supervised node classification [18, 37], link prediction [14, 50], and social cascade prediction [44, 49].

Among existing works in GNNs, our work is closely related to the PPNP algorithm proposed in [19] and the MONSTOR algorithm proposed in [20]. PPNP separates the feature transformation and information propagation into independent stages and computes an approximate stationary distribution of the personalized page rank (PPR) [34] to propagate each node's prediction to other nodes on the graph. The propagation scheme is as follows:

$$\begin{aligned} Z^{(0)} &= f_\theta(X) \\ Z^{(k)} &= (1-\alpha)\hat{\tilde{A}}Z^{(k-1)} + \alpha Z^{(0)} \\ Z^{(K)} &= \text{softmax}\left((1-\alpha)\hat{\tilde{A}}Z^{(K-1)} + \alpha Z^{(0)}\right) \end{aligned} \tag{3}$$

where f_θ is a multi-layer nonlinear function, X is the initial feature matrix, α is the teleport probability in PPR, and $\hat{\tilde{A}}$ is the symmetrically normalized adjacency matrix with self-loops of the graph. PPNP motivates our work as we propose to combine the characteristics of the diffusion models and the iterative propagation process in a two-stage framework.

MONSTOR focuses on the incremental influence spread estimation of nodes under IC model based on a stacked structure of multiple GNNs. However, the model weights the neighbor node's features according to the influence strength in the aggregation stage, ignoring the characteristics of diffusion models. Furthermore, the

Table 1: Frequent notations used across the paper

Notation	Description
$\mathcal{G}, \mathcal{V}, \mathcal{E}$	The social graph, the node set, the edge set
S	The seed set on social graph
P	The influence propagation probability matrix
D	A diffusion instance on target graph
$\zeta_S(n_i)$	The susceptibility of node i under seed set S
$\sigma(S)$	The total influence spread of seed set S
X	The constructed feature matrix
$\tilde{\zeta}_i$	The *approximate susceptible probability* of node i

estimation error accumulates with the number of GNNs increases. In this work, we estimate the susceptibility of each node using a single neural network and propagate the estimations leveraging the characteristics of the diffusion model to obtain precise estimations.

3 PROBLEM FORMULATION

In this section, we introduce the diffusion model and the problem formulation for susceptibility estimation. For ease of presentation, we mainly focus on IC model but our proposed framework can be adapted to support other diffusion models, like LT model. To ease the representation, frequently used notations are listed in Table 1.

3.1 The IC Model

For a given graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is the node set and $\mathcal{E}$ is the edge set, with $|\mathcal{V}| = n$. Each $e_{ij} \in \mathcal{E}$ is associated with an influence probability p_{ij}, indicating the probability of node i influence node j in the next step, if i is influenced in the current step. We denote P as the influence strength matrix with $P_{n\times n} = (p_{ij})_{n\times n}$. Under IC model, the influence propagates from the initial seed nodes S at timestep 0. At each timestep $t > 0$, the influenced (or activated) node i in timestep $t-1$ propagate influence to their out-neighbor j with probability p_{ij}. Note that each activated node only has one chance to activate its neighbors and remains to be in the active state. The propagation process terminates at timestep t if is are no newly activated node.

3.2 The Susceptibility Estimation Problem

Given IC model, we use D to represent a diffusion instance and denote the state of node i on instance D by $I_{S,D}(n_i)$. If n_i is influenced by seed S in instance D , $I_{S,D}(n_i) = 1$ and 0 otherwise. The susceptibility of node i is represented by $\zeta_S(n_i) = \mathbb{E}_{D\sim p(D)}[I_{S,D}(n_i)]$. The *Susceptibility Estimation Problem* aims to estimate $\zeta_S(n_i)$ for each node n_i. We denote the influence spread of seeds S as $\sigma(S)$. One can see that $\sigma(S) = \sum_{n_i\in\mathcal{V}} \zeta_S(n_i)$.

4 DEEPIS

In this section, we propose the **D**eep **I**nfluence **S**pread Estimation (DeepIS) model . DeepIS consists of two stages, i.e., (1) construct features to feed a GNN for coarse-grained susceptibility estimation of each node. (2) propagate estimations, which propagates each node's estimated susceptibility to neighbors through an iterative process. Finally, we compute the loss between the estimations after these procedures with the training labels, to optimize the model in an end-to-end manner. Note that we refer to the feature construction and coarse-grained computation as the *GNN stage*, while the estimation propagation as the *propagation stage*. We demonstrate the framework of the DeepIS model in Fig. 1. We describe the two stages in the following sections.

4.1 GNN Stage

Feature construction. Given the influence strength matrix P and the initial seed nodes. We can represent the seed nodes S as a multi-hot vector $\boldsymbol{x}$, with $\boldsymbol{x}[i] = 1$, if $n_i \in S$, otherwise $\boldsymbol{x}[i] = 0$.

The matrix P preserves both the graph topology and the influence strengths, while $\boldsymbol{x}$ preserves the seeds information. We denote the node's susceptible probability vector as $\boldsymbol{\zeta}_S$, i.e., $\boldsymbol{\zeta}_S = [\zeta_S(n_1), \zeta_S(n_2), ...]^T$. Theoretically, $\boldsymbol{\zeta}_S$ and the influence spread $\sigma(S)$ are completely determined by P and $\mathbf{x}$.

Since P and $\boldsymbol{x}$ involve sufficient information for computing the objective $\boldsymbol{\zeta}_S$ and $\sigma(S)$, we consider leverage P and $\boldsymbol{x}$ to construct the features. We first introduce the following definition.

Definition 4.1 (d-step influence probability). A node's d-step influence probability is the activation probability at timestep d.

Note that $(P^T)^d\boldsymbol{x}$ is an upper bound of the d-step influence probability of all nodes under IC model [51], since $(P^T)^d$ includes all paths from an arbitrary seed to an arbitrary target node with length d. Based on this observation, we utilize the matrix power of P^T and $\boldsymbol{x}$ to construct the **feature matrix** X for all nodes, i.e.,

$$X = [\boldsymbol{x}, P^T\boldsymbol{x}, (P^T)^2\boldsymbol{x}..., (P^T)^d\boldsymbol{x}] \tag{4}$$

Node estimation. Once the feature matrix X is obtained, we adopt a nonlinear neural function f_θ to predict each node's $\zeta_S(n_i)$, where θ is the function parameter. In this work, we adopt a two-layer fully connected neural network as the f_θ. Our studies show that the simple f_θ provides reasonable results and computation effectiveness. Specifically, we calculate the estimations of all node as follows:

$$\begin{aligned} f_\theta(X) &= \text{Sigmoid}(\text{Relu}(XW_1 + \boldsymbol{b_1})W_2 + \boldsymbol{b_2}) \\ \hat{\boldsymbol{y}}_i &= f_\theta(X[i,:]) \end{aligned} \tag{5}$$

Note that the choice of the function f_θ is flexible. We may integrate other prediction models to substitute the f_θ adopted above, e.g., GCNs [18] or attention-based graph models [43].

4.2 Propagation Stage

We propose the propagation scheme that draws the intuition from the random walk. We first describe the stationary distribution of random walk process and analyze the difference between random walk and random influence diffusion. Then we propose the propagation scheme for DeepIS. Finally, we conduct some theoretical analysis on the convergence property of the propagation process.

Propagation scheme. Previous works utilize the stationary distribution of random walk to propagate information to neighbor nodes [19]. Meanwhile, the diffusion process has differences compared against the random walk. For the random walk, the probability of a node being visited in a given timestep is the summation of its neighbor's probabilities multiplying the transition matrix. The stationary distribution $\boldsymbol{\pi}$ satisfies the following equation [19]:

$$\boldsymbol{\pi} = P\boldsymbol{\pi} \tag{6}$$

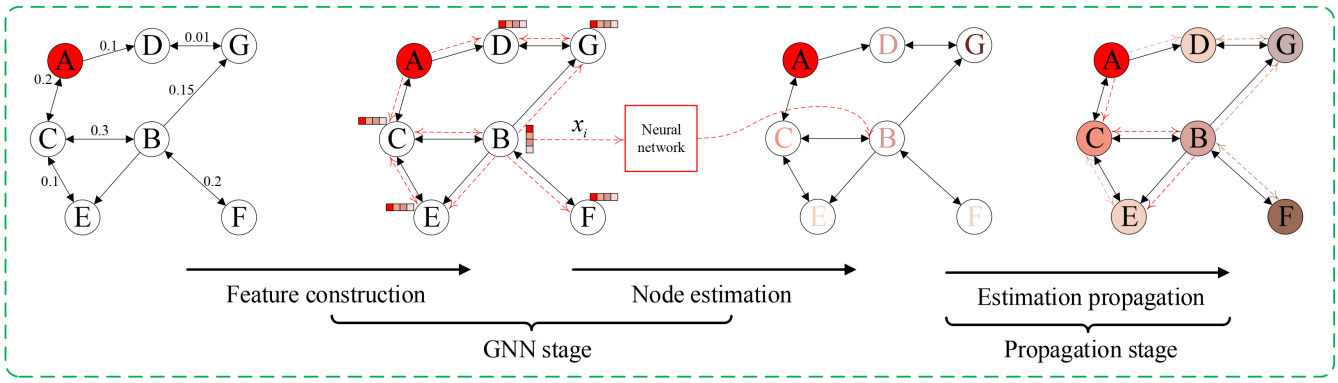

Figure 1: The framework of the proposed DeepIS model for susceptibility estimation. Firstly, the model constructs each node's feature vector according to influence strengths and the seed nodes (the red node). Secondly, a nonlinear neural function maps each node's feature vector to a probability in $[0, 1]$. Finally, each node's result propagates to its neighbor nodes except the seed nodes to obtain the final estimation.

For the random walk with restart probability α, the stationary distribution matrix $\mathbf{\Pi}$ satisfies (7), [19].

$$\mathbf{\Pi} = (1-\alpha)P\mathbf{\Pi} + \alpha \boldsymbol{I}_n \tag{7}$$

In the random walk, a node can be passed for multiple times, while in influence diffusion, once a node is influenced, it cannot be influenced twice. The influence spread process is intrinsically different with random walk.

Furthermore, motivated by the stationary distribution of random walk, we propose the following *approximate stationary distribution* $\tilde{\zeta}$ to *approximate* stationary probabilities under IC diffusion model, which satisfy the relation (8).

$$\tilde{\zeta}_i = 1 - \prod_{n_j \in \mathcal{N}(n_i)} (1 - P_{ji}\tilde{\zeta}_j) \tag{8}$$

$\mathcal{N}(n_i)$ in (8) denotes the in-neighbors of node n_i. Equation (8) means that for node n_i, the susceptible probability $\tilde{\zeta}_i$ of node n_i is *approximated* by its in-neighbors' susceptibilities. We note that, to adapt our approach for other diffusion models, one only needs to update Equation (8). For example, we can design the approximate susceptible probability for LT model as:

$$\tilde{\zeta}_i = \sum_{n_j \in \mathcal{N}(n_i)} P_{ji}\tilde{\zeta}_j \tag{9}$$

Next we define the propagation function $g(\cdot)$ and describe the propagation scheme. $g(\cdot)$ is defined as follows:

$$g(\boldsymbol{x}) = \begin{pmatrix} g(x_1) \\ g(x_2) \\ \cdots \\ g(x_n) \end{pmatrix} = \begin{pmatrix} 1 - \prod_{n_j \in \mathcal{N}(n_1)} (1 - P_{j1}x_j) \\ 1 - \prod_{n_j \in \mathcal{N}(n_2)} (1 - P_{j2}x_j) \\ \cdots \\ 1 - \prod_{n_j \in \mathcal{N}(n_n)} (1 - P_{jn}x_j) \end{pmatrix} \tag{10}$$

The propagation scheme is formulated in (11), which originates from the relation in (8).

$$\begin{aligned} \hat{\boldsymbol{y}}^{(0)} &= \hat{\boldsymbol{y}} \\ \hat{\boldsymbol{y}}^{(1)} &= g(\hat{\boldsymbol{y}}^{(0)}) \\ \hat{\boldsymbol{y}}^{(q)} &= g(\hat{\boldsymbol{y}}^{(q-1)}) \end{aligned} \tag{11}$$

Note that q denotes the iteration number.

Note that $g(x_i)$ is determined by in-neighbors of node n_i, hence one iteration essentially propagates each node's information into its one-hop neighbors. After q iterations of propagation, we output the $\hat{\boldsymbol{y}}^{(q)}$ as the final results.

The AGGREGATE and COMBINE in (12) summarize the propagation stage.

$$\begin{aligned} a_i &= \text{AGGREGATE}\left(\{x_j, j \in \mathcal{N}(n_i)\}\right) = g(x_i) \\ h_i &= \text{COMBINE}\left(\{a_i, x_i\}\right) = \begin{cases} a_i, & n_i \in S \\ 1, & n_i \notin S \end{cases} \end{aligned} \tag{12}$$

Note that (12) shows that for seed nodes, we do not combine the neighbor information since the susceptibility is always 1.

Propagation analysis In the following, we give the fixed point existence and the convergence analysis of the iteration function $g(\cdot)$, to study the choice of iteration number q. Note that a fixed point $\boldsymbol{x}^*$ satisfies $\boldsymbol{x}^* = g(\boldsymbol{x}^*)$. We first introduce the following fixed point theorem.

Theorem 1 ([2]). *Let $D = \{(x_1, \cdots, ..., x_n)^T | a_i \le x_i \le b_i\}$, for some collection of contents of $a_1, \cdots, a_n$ and $b_1, \cdots, b_n$. Suppose $g(\cdot)$ is a continuous function from $D \subset \mathbb{R}^n$ into $\mathbb{R}^n$ with property that $g(\boldsymbol{x}) \in D$ whenever $\boldsymbol{x} \in D$. Then $g(\cdot)$ has a fixed point in D.*

Suppose that all the component functions of $g(\cdot)$ have continuous partial derivatives and a constant $K \le 1$ exists with

$$\left|\frac{\partial g_i(\boldsymbol{x})}{\partial x_j}\right| \le \frac{K}{n}, \quad \forall \boldsymbol{x} \in D$$

for all $j = 1, \cdots, n$, and all component function $g_i(\cdot)$. Then the sequence $\{\boldsymbol{x}^{(k)}\}_{k=0}^{\infty}$ defined by a $\boldsymbol{x}^{(0)} \in D$ and generated by

$$\boldsymbol{x}^{(k)} = g(\boldsymbol{x}^{k-1}), \quad \forall k \ge 1$$

converges to the unique fixed point $\boldsymbol{p} \in D$.

Based on the Theorem 1, we present the following propositions.

Proposition 4.2. *$g(\cdot)$ in (10) has a fixed point in $[0, 1]^n$.*

Proof. Let $D = [0,1]^n$ and $P_{ij} \in [0,1], \forall i,j$. One can see that $g(\cdot)$ is continuous. For $\forall \boldsymbol{x} \in D$, we have $g(x_i) \in [0,1], \forall i$. Hence we have $g(\boldsymbol{x}) \in D$, i.e., $g(\cdot)$ has a fixed point in D. □

Proposition 4.3. *The iteration process in* (11) *may not converge for an arbitrary influence probability matrix* P.

Proof. The partial derivatives of $g_i(\boldsymbol{x})$ w.r.t x_j is computed as:

$$\begin{aligned}\frac{\partial g_i(\boldsymbol{x})}{\partial x_j} &= \frac{\partial\left(1-\prod_{n_k\in\mathcal{N}(n_i)}(1-P_{ki}x_k)\right)}{\partial x_j}\\ &= \frac{\partial\left(1-\prod_{k=1\to n}(1-P_{ki}x_k)\right)}{\partial x_j}\\ &= \frac{\partial\left(1-(1-P_{ji}x_j)\prod_{k=1\to n,k\neq j}(1-P_{ki}x_k)\right)}{\partial x_j}\\ &= P_{ji}\prod_{k=1\to n,k\neq j}(1-P_{ki}x_k)\end{aligned}$$

Since $x_k \in [0,1]$, we have $\frac{\partial g_i(\boldsymbol{x})}{\partial x_j} \in [P_{ji}\prod_{k=1\to n,k\neq j}(1-P_{ki}), P_{ji}]$. For an arbitrary matrix P, the condition $P_{ji} \leq \frac{1}{n}$ may not be satisfied. Hence the iteration process in (11) may not converge. □

Propositon 4.2 and 4.3 reveal that the propogation iteration process has a fixed point. However, the iteration process may not converge for an arbitrary graph influence probability matrix P. Hence we should not set the iteration number q too large. In practice, an iteration number $q \leq 5$ leads to satisfactory results in experiments, and we will study the iteration effect in section 6.4.

4.3 End-to-end Training

Since the propagation function $g(\cdot)$ is differentiable, we could integrate the propagation scheme into model training and utilize the final output $\hat{\boldsymbol{y}}^{(q)}$ to compute loss. Note that we omit the superscript (q) in the following for conciseness.

We adopt the mean square error on training cascades considering the probability estimation error on each node, i.e.,

$$L_{\text{MSE}} = \frac{1}{M}\sum_{m=1}^{M}\|\hat{\boldsymbol{y}}_{(m)} - \boldsymbol{y}_{(m)}\|_2 \tag{13}$$

where M is the number of training cascades, i.e., the training set $T = |\{C_1, C_2, \cdots, C_M\}|$. Each cascade $C = \{\boldsymbol{x}, \boldsymbol{y}\}$ includes the initial multi-hot seed vector $\boldsymbol{x}$ and the groundtruth target probability vector $\boldsymbol{y}$.

We also measure the influence spread error leveraging the mean relative square error (MRSE). The MRSE reflects the graph-level estimation performance, with optimization robustness and differentiability.

$$L_{\text{MRSE}} = \frac{1}{M}\sum_{m=1}^{M}\left(\frac{\|\hat{\boldsymbol{y}}_{(m)}\|_1 - \|\boldsymbol{y}_{(m)}\|_1}{\|\boldsymbol{y}_{(m)}\|_1}\right)^2 \tag{14}$$

We describe the final objective to be optimized as follows:

$$\text{Loss} = \underbrace{L_{\text{MSE}}}_{\text{node lever error}} + \underbrace{\lambda L_{\text{MRSE}}}_{\text{graph lever error}} + \underbrace{\gamma\|\theta\|_2}_{\text{regularization term}} \tag{15}$$

Table 2: Dataset statistics. Avg. p is the average probability.

Dataset	Type	$\lvert\mathcal{V}\rvert$	$\lvert\mathcal{E}\rvert$	Avg. p

which consists of three components, with hyperparameters λ and γ. The L2 regularization term aims to mitigate the over-fitting and facilitates the convergence process.

5 EXPERIMENTAL SETUP

In this section, we compare our method with several state-of-the-art GNN models and the MC simulation under several evaluation metrics to measure the prediction performance. We also report the performance of `DeepIS` when used as a subroutine in IM algorithms. Note that we implement all algorithms with python3.7 and run on a server with a Intel Xeon E5-2620 CPU.

5.1 Datasets

We adopt four commonly used datasets: CORA-ML [31], CITESEER [38], PUBMED [32], and MS-ACADEMIC [40]. For each dataset, we select the largest connected component for our experiments. Since the groundtruth influence propagation probabilities between nodes are unavailable on these datasets, previous works generate these parameters manually [5, 46]. Similarly, we generate these influence parameters from a discrete set [0.001, 0.01, 0.05, 0.1, 0.15, 0.2, 0.3] with uniform probabilities. We summarize the statistics of datasets in Table 2.

For each dataset, we generate the propagation cascades according to the following two strategies. Firstly, we generate seed sets with the size of 50, 100, 150, 200, 250, 300. For each seed size, we generate 100 random seed vector $\boldsymbol{x}$. We repeat 10000 MC simulations for each seed set to obtain the groundtruth susceptible probability vector $\boldsymbol{y}$. Each cascade instance C consists of the $\boldsymbol{x}$ and the $\boldsymbol{y}$, i.e., we construct C as a $|\mathcal{V}| \times 2$ matrix, with $C[:,0] = \boldsymbol{x}$ and $C[:,1] = \boldsymbol{y}$. We randomly sample 80% of these cascades as the train set, 10% as the validation set and 10% as the test set. Secondly, to avoid small influence probabilities of random seeds, we further compute the top-K nodes with the highest degrees as seed sets for each seed size as test sets. We will compare the model's performance on two kinds of seed sets respectively.

5.2 Baselines

We compare the following GNN approaches with `DeepIS`.

- GCN [18]. GCN utilizes the normalized Laplacian matrix to average each node's feature with neighbor's features, and transform these averaged features with a shared parameter matrix.
- GraphSAGE[13]. GraphSAGE aggregates each node's neighbor features and concatenates the aggregated features with node's self-features. GraphSAGE transforms node features in an inductive manner and is applicable on an unseen graph, differing from that of GCN.

- GAT [43]. GAT improves the performance of GraphSAGE by introducing the attention mechanism. The attention mechanism calculates aggregation weights between nodes in the aggregation layer, introducing flexibility and directionality for different nodes.
- SGC [47]. SGC simplifies previous GCN-like models by propagating node features in a preprocessing stage, then predicting each node's target value with a simple logistic regression. The SGC follows a similar philosophy with our work to some extent, i.e., separating the propagation and prediction.
- MONSTOR [20]. MONSTOR aims to estimate the total influence spread of a seed set by stacking multiple GCN models. One GNN model predicts the incremental influence spread of one-step influence propagation based on former GNN model's outputs.

Transductive vs Inductive. For the transductive methods, including GCN and SGC, we train on four datasets. For the inductive methods, including our DeepIS, GraphSAGE, GAT, and MONSTOR, we train on the CORA-ML and test on the other three datasets.

Once the independent susceptible probabilities are obtained, the total influence spread is easily calculated by summation. Since the influence spread calculation is a key component in the IM problem, we further compare the influence spread and running time of two representative IM algorithms, i.e., UBLF [51], and CELF [21], when invoking the MC simulation as the subroutine and invoking DeepIS model as the subroutine. We denote each scenario as UBLF_{MC} (CELF_{MC}) and $\text{UBLF}_{\text{DeepIS}}$ ($\text{CELF}_{\text{DeepIS}}$), respectively.

5.3 Implementation Details

For GCN and GraphSAGE, we adopt a 2-layer structure, as reported in their original papers [13, 18]. For GAT, we set the number of attention heads to 4 and the dimension of each attention channel to 8 [43]. For SGC, we set the iteration number in the preprocessing stage to 2, as reported in the original work. For MONSTOR, We set the number of stacks to 3, and for each stack, we adopt a 2-layer GCN network, as reported in [20]. For the proposed DeepIS model, we leverage a 2-layer MLP as the fucntion $f(\cdot)$, as stated in section 4.1. For the feature dimension $d+1$ in feature construction stage and the iteration number q in propagation stage, we vary d in $[2, 5]$ and vary q in $[1, 4]$. We will discuss the effects of these important hyperparameters in Section 6.4. Note that the number of hidden units for all the baseline models and the DeepIS is set to 64. We provide the identical feature matrix constructed using Equation (4) for all models for fair comparison.

5.4 Evaluation Metrics

We adopt several metrics to evaluate the performance of different methods. Note that T denotes the number of test instances.

5.4.1 Mean Error (ME). The *mean error* measures the mean absolute susceptibility estimation error on each node.

$$\text{ME} = \frac{1}{T}\sum_{t=1}^{M}\frac{1}{|\mathcal{V}|}\sum_{i=1}^{|\mathcal{V}|}|\hat{\boldsymbol{y}}_i^{(t)} - \boldsymbol{y}_i^{(t)}| \tag{16}$$

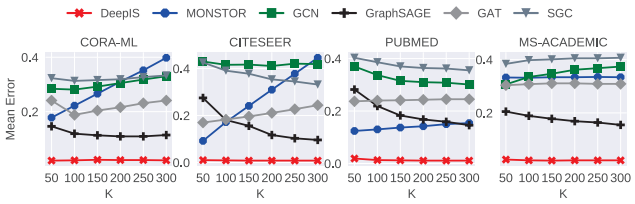

Figure 2: The mean error of different methods on all datasets with random seeds(IC).

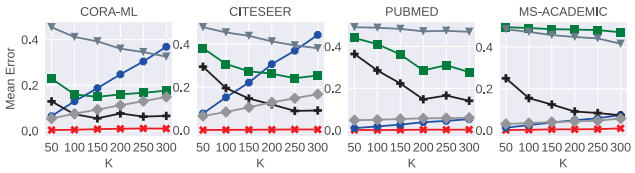

Figure 3: The mean error of different methods on all datasets with random seeds(LT).

5.4.2 Total Error (TE). The *total error* measures the mean absolute total influenced nodes estimation error on graph level.

$$\text{TE} = \frac{1}{T}\sum_{t=1}^{T}\left(\left|\sum_{i=1}^{|\mathcal{V}|}\hat{\boldsymbol{y}}_i^{(t)} - \sum_{i=1}^{|\mathcal{V}|}\boldsymbol{y}_i^{(t)}\right|\right) \tag{17}$$

5.4.3 Running Time (RT). We compare the average running time between $\text{UBLF}_{\text{DeepIS}}$ ($\text{CELF}_{\text{DeepIS}}$) and UBLF_{MC} (CELF_{MC}). RT essentially reveals the speed comparison between DeepIS and MC. All compared methods are executed under the single thread setting.

5.4.4 Influence Spread (IS). We compare the influence spread performance between $\text{UBLF}_{\text{DeepIS}}$ ($\text{CELF}_{\text{DeepIS}}$) and UBLF_{MC} (CELF_{MC}). IS metric evaluates the proposed DeepIS's performance when running as a subroutine in IM algorithms.

6 EXPERIMENTAL RESULTS

In this section, we firstly compare the ME and TE of all methods on four datasets. Besides, we substitute MC in two IM algorithms with DeepIS to compare the efficiency and influence spread. We analyze the effect of several hyperparameters in the model further. Finally, we show the effect of the propagation stage intuitively.

6.1 Estimation Error on Random Seeds

The mean error of all methods on IC and LT models are demonstrated in Fig. 2 and Fig. 3, respectively. Fig. 2 demonstrates the mean error of all methods on different datasets with varying seed set sizes. We can see that other GNN methods perform unsatisfactorily for this problem. GraphSAGE achieves the smallest estimation error in most scenarios among the GNN baselines. However, the mean error of GraphSAGE exceeds 0.1, which is a relatively large deviation from the groundtruth. In all scenarios, DeepIS achieves the smallest mean error compared with the baselines. The estimation error of DeepIS is stable and fluctuates around 0.02 for different scenarios, which is on average five times smaller than baselines.

For the total error in the graph level, Fig. 4 and Fig. 5 show the results of all methods with different seed sizes on IC and LT models,

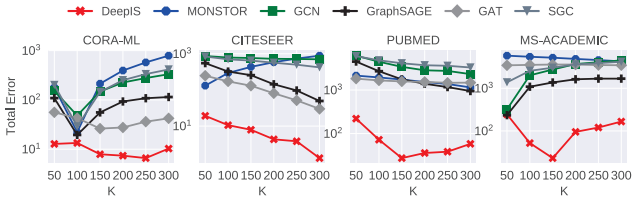

Figure 4: The total error of different methods on all datasets with random seeds(IC).

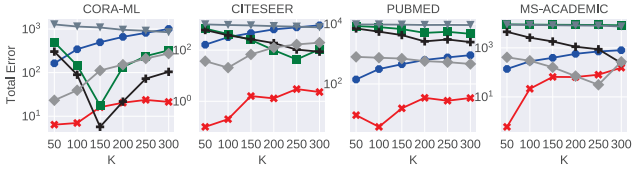

Figure 5: The total error of different methods on all datasets with random seeds(LT).

respectively. We can see that the results of total error generally align with the mean error. While there exist mismatches since the total error is not strictly equal to the summation of absolute errors of all nodes. For example, on the CORA-ML dataset under IC model in Fig. 4, other models achieve the best total error and are adjacent to DeepIS with seed size 100. However, in Fig. 2, their mean errors are much larger than that of DeepIS, revealing that their predictions are inaccurate on most nodes, and the relatively small total errors are obtained due to the cancellation of errors when summing estimations across different nodes.

6.2 Estimation Error on High Degree Seeds

For high-degree seeds, Fig. 6 and Fig. 7 demonstrates the mean error on IC and LT models, respectively. Fig. 8 and Fig. 9 show the total error on two models, respectively. High degree seeds are more likely to induce high susceptible probabilities than randomly selected seeds. In our experiments, the mean susceptible probability is larger than 0.15 for these datasets. We can see that, in Fig. 6 and Fig. 7, DeepIS remains to produce the smallest mean error compared with other baselines. The results are similar with those of Fig. 2 and Fig. 3. The mean error of DeepIS fluctuates between 0.01 and 0.02, while other baselines are larger than 0.1. Fig. 8 and Fig. 9 show that in most settings, DeepIS obtains competitive performance for the total error. Some baselines achieves smaller total error under some settings. However, as stated in Sec. 6.1, the smaller total errors are achieved by the cancellation of different node's errors.

The results in Sections 6.1 and 6.2 reveals, DeepIS achieves on average five times smaller mean error compared with the baselines. We interpret the inferior performance of the baseline GNN models as two-fold: First, most of these models are devised for the node classification problem, while estimating the susceptible probability for each node is more challenging and complicated than the classification problem. Second, each node's target value is determined by the underlying propagation model, while only the proposed DeepIS considers the specific diffusion characteristics of the propagation in the model construction and inference.

Table 3: The hyperparameters

Hyperparameter	Description	Values
d	Feature dimension	2, 3, **4**, 5
q	Iteration number	1, **2**, 3, 4
λ	Weight of L_{MRSE}	**1e-4**, 1e-3, 1e-2, 1e-1
γ	Weight of $\|\|\theta\|\|_2$	1e-5, **1e-4**, 1e-3, 1e-2

6.3 Performance in IM Algorithms

In this section, we report the model's performance when substituting MC with DeepIS in IM algorithms on the CORA-ML dataset. Fig. 10 and Fig. 11 illustrates the influence spread comparison on IC and LT models, respectively. The influence spread of computed seeds with each size is calculated using MC with 10000 repeats. For IC model in Fig. 10, we can see that the $\text{UBLF}_{\text{DeepIS}}$ achieves almost identical influence spread with that of UBLF_{MC} for each seed size. The results are similar for $\text{CELF}_{\text{DeepIS}}$ and CELF_{MC}. For LT model in Fig. 11, the final influence spread of $\text{UBLF}_{\text{DeepIS}}$ is also close with that of UBLF_{MC}. The influence spread comparison between $\text{CELF}_{\text{DeepIS}}$ and CELF_{MC} is similar. Generally, the results in Fig. 10 and Fig. 11 reveal that, substituting MC with DeepIS has minor effects on the quality of seeds calculated by IM algorithms.

As mentioned above, substuiting MC with DeepIS essentially does not affect the execution workflow of CELF and UBLF algorithms. Hence the running time comparision between $\text{CELF}_{\text{DeepIS}}$ ($\text{UBLF}_{\text{DeepIS}}$) and CELF_{MC} (UBLF_{MC}) reflacts the efficiency between DeepIS and MC. Fig. 12 and Fig. 13 illustrates the running time comparison under IC and LT model, respectively. For IC model in Fig. 12, $\text{UBLF}_{\text{DeepIS}}$ consumes about 0.75h to obtain 300 seeds, while UBLF_{MC} requires about 70 hours. $\text{CELF}_{\text{DeepIS}}$ consumes about 1.9h for 300 seeds while CELF_{MC} requires about 180 hours. For LT model, the results are similar, $\text{UBLF}_{\text{DeepIS}}$ and $\text{CELF}_{\text{DeepIS}}$ requires less than 0.8h, while UBLF_{MC} and CELF_{MC} requires about 60 hours. Comparing Fig. 12 and Fig. 13, we can see that algorithms invoking DeepIS reduces about two magnitudes of running time compared with their counterparts invoking MC. In other words, DeepIS estimates influence spreads about 100 times faster under IC model, and about 80 times faster under LT model. We can further enable real-time analysis by implementing DeepIS under GNN parallel processing systems, e.g., [29].

6.4 Hyperparameter Analysis

In this section, we analyze the effects of several import hyperparameters of the DeepIS model. We list the information of hyperparameters in Table 3, and conduct experiments on the CORA-ML dataset under IC model.

Fig. 14 shows the effects of d. We can see that larger d achieves lower mean error since larger d provides more information of the propagation. However, larger d results in higher computational cost. Hence, we set the default d to 4 to balance effectiveness and efficiency. Fig. 15 illustrates the effect of q. The results reveal that $q = 2$ and $q = 3$ outperforms other settings. The results in Fig. 15 reveals that we do not need to iterate too many times (less than 5) in the propagation stage. We set $q = 2$ as the default value considering diverse scenarios. Fig. 16 shows small λ performs well for the mean error metric, since small λ forces the model to focus on the node-level error. Hence, we choose λ = 1e-4 as the default value. Fig. 17 adjusts the weight of L2 regularization. We can see that it is suitable to set γ in the range [1e-5, 1e-3], since γ =1e-2 results in obviously larger mean error than other settings. The reason may lie in the underfitting of the model for a large L2 penalty. Hence, we set γ =1e-4 as the default value.

6.5 Discussion of Two-Stage Approach

In this section, we discuss the effectiveness of the propagation stage integrated in training of DeepIS. We randomly select 300 seeds on the CORA-ML dataset and compute susceptibilities of all nodes using MC under IC model as groundtruth. To illustrate the comparison intuitively, we plot susceptibility histograms of DeepIS's estimations (with/without the second stage) and groundtruth in Fig. 18. In the first row, the horizontal axis represents the susceptible probabilities and the vertical axis represents the number of nodes with the same value. The second row shows the relation between estimation and target values, with the horizontal axis representing the estimated susceptible probabilities and the vertical axis representing the groundtruth. Each scatter in the second row respresnts one node. Comparing the second column with the third column, we can see that the propagation component reduces the estimation error for most nodes effectively. The scatter points in the third column are highly concentrated around the ideal green line in the first column. We argue that the model gains prediction benefits from the propagation module, which cooperate with the first prediction module to make the whole model complement the propagation dynamics of the specific diffusion model during training.

7 CONCLUSION AND FUTURE WORKS

In this paper, we propose the DeepIS model to estimate the susceptibility of independent network individuals effectively. We consider this problem as a node regression task in the graph learning perspective. DeepIS combines GNN structures and characteristics of influence diffusion models to perform co-training. Experimental

results reveal that DeepIS predicts both each node's susceptible probability and total influenced nodes accurately. The model also performs well as a subroutine in IM algorithms. As for future works, an interesting direction is generalizing DeepIS to predict susceptibility for topic-aware [4, 8] and dynamic social graphs [39, 45].
